

6. What are Python data types?

Python data types define the kind of value a variable stores. Common types are int (whole numbers), float (decimal numbers), str (text), bool (True/False), list, tuple, set, and dict. Example: age=20, price=99.5, name='Alice'.

7. What is type casting?

Type casting means converting one data type into another using functions like int(), float(), str(), and bool(). Example: int('10') converts the string '10' into the integer 10.

8. What is the difference between local and global variables?

A local variable is created inside a function and can only be used there. A global variable is created outside a function and can be accessed throughout the program.

9. What are Python keywords?

Keywords are reserved words that have special meaning in Python and cannot be used as variable names. Examples include if, else, for, while, def, class, return, and True.

10. What are comments in Python?

Comments are notes for humans and are ignored by Python. Use # for a single-line comment and triple quotes for multi-line documentation strings.
